Keywords: Magnetic properties, specific heat, rare earth ternary alloys

Abstract. The results of magnetic and specific heat studies are reviewed and discussed for the series of RZnSn₂ (R = Y, Er and Lu) compounds crystallizing in the same tetragonal HfCuSi₂-type of structure. A sharp peak in the specific heat of ErZnSn₂ compound is indicative for magnetic ordering of Er moments at 5.0 K, being in agreement with its established antiferromagnetic nature. The estimated magnetic entropy S_{magn} contribution is less than that expected for the ground state $J = 15/2$ multiplet of Er³⁺.

Introduction

The new ternary intermetallic compounds RZnSn₂ (R = Y, Gd, Tb, Dy, Ho, Er, Tm, Lu) have been recently synthesized. It was shown that they crystallize in the tetragonal HfCuSi₂ structure type [1]. These stannides belong to the rich family of R-T-X intermetallics, which present a variety of crystal and magnetic structures and a plethora of interesting physical properties, including magnetism, superconductivity and intermediate valency. Since Zn and Sn atoms do not carry magnetic moments themselves, magnetic properties of RZnSn₂ compounds are governed by the rare earth moments, by their conduction - electron mediated exchange interactions, and by the effects of crystalline electric fields (CEF) acting on the 4f states. Hence, the knowledge of CEF effects is of special interest. Especially, for a quantitative interpretation of the temperature dependence of the specific heat and of the entropy the knowledge of the actual level scheme, i.e., of the CEF parameters is needed, but no experimental results concerning this issue have been published so far for the RZnSn₂ series.

The aim of this work is to present and discuss some of preliminary magnetic and specific heat data measured within wide temperature range by means of PPMS for three RZnSn₂ (R = Y, Er, and Lu) intermetallics.

Experimental

The polycrystalline RZnSn₂ (R = Y, Er and Lu) samples have been prepared as described previously [1] and their crystal structures were determined from powder diffractograms using the FullProf program [2] for Rietveld refinements.

The bulk magnetic and specific heat measurements were performed in the temperature range 1.9 K - 300 K by means of the vibrating sample magnetometer (VSM) and the heat capacity (HC) options of the Quantum Design physical property measurement system (PPMS). The reported here specific heat studies were made in zero external magnetic field. Special care was taken to correct in a proper way the raw HC results taking into account of the specific heat contribution originating from the adhesive addenda (*Apiezon N*) that is used to couple a given sample to the PPMS HC platform.

Experimental results and discussion

X-ray diffraction analysis showed that all the investigated compounds crystallize with the HfCuSi_2 -type structure, space group $P4/nmm$ [1].

Among the studied compounds only ErZnSn_2 exhibits a clear paramagnetic to antiferromagnetic phase transition in the experimental temperature range at $T_N = 5.0$ K [1]. The antiferromagnetic character of this compound correlates with its negative paramagnetic Curie temperatures $\theta_p = -8.8$ K and a metamagnetic behaviour of its magnetization curve recorded at the lowest temperatures [1]. The observed increase of mass magnetic susceptibility $\chi_\sigma(T)$ dependence below T_N (Fig. 1) could signalize another phase transition at lower temperature (out of experimental range), but most

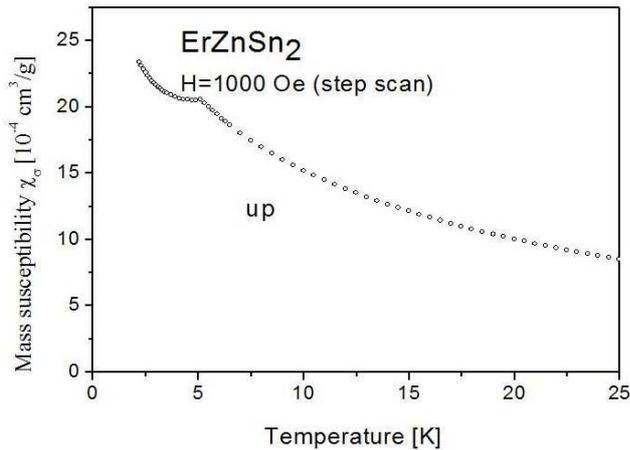

Fig. 1. Temperature dependence of the magnetic susceptibility for ErZnSn_2 , measured with rising temperature in an $H = 1000$ Oe external magnetic field. The anomaly points to an antiferromagnetic transition, agreeing with previous low field ZFC data (Fig. 8b in ref. [1]).

probably induced by the moments reorientation in magnetic field used ($H = 1000$ Oe), since this behavior is absent in the data taken at $H = 50$ Oe [1]. The derived magnetic effective moment, $\mu_{\text{eff}} = 10.47 \cdot \mu_B$, is higher than the expected theoretical value for the Er^{3+} free-ion value ($\mu_{\text{eff}}(\text{theor.}) = g\mu_B[J(J+1)]^{1/2} = 9.58 \mu_B$) and a possible reason for the observed excess has already been discussed [1], being tentatively related, at least in part, to the contribution originated from the delocalized d -electrons of Zn. Especially, similar excess of magnetic effective moment is well established for ternary Gd-T-X compounds [3-12], but in this case the main contribution to the excess arises from the Gd $5d$ electrons and it is induced via $4f$ - $5d$ exchange interactions, while the contribution coming from the conduction d electrons of a given T-element plays a secondary role.

The specific heat results are shown in Figs. 2a and 2b for all title compounds. Among them only ErZnSn_2 shows a sharp λ type anomaly at $T_N = 5.0$ K, being exactly as the Néel temperature obtained from the low field magnetic measurements.

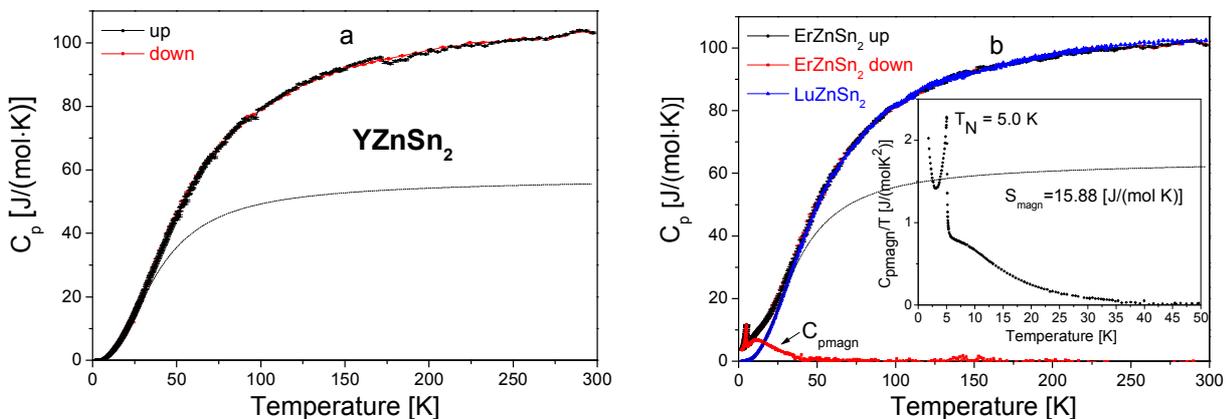

Fig. 2. Temperature dependencies of the specific heat (C_p) for the YZnSn_2 (a) and ErZnSn_2 together with superimposed LuZnSn_2 and their difference marked as the $C_{p,\text{magn}}$. (b). Inset in Fig. 2b shows the low temperature part of $C_{p,\text{magn}}/T$ vs. T dependence for ErZnSn_2 . The dashed lines are fits to YZnSn_2 and LuZnSn_2 data, respectively, with the standard Debye expression for θ_D values obtained at low temperatures (i.e. $\theta_D = (155.5 \pm 4.0)$ K and $\theta_D = (148.0 \pm 3.0)$ K for Y and Lu compounds, respectively, see the text below).

As it is seen from Fig. 2, the data collected with rising (up) and decreasing temperature (down) show no hysteresis. To separate the magnetic contribution, C_{pmagn} , from the total specific heat measured for ErZnSn_2 , C_p , the following expression was used: $C_p = C_{lat} + C_{pmagn}$, where C_{lat} represents the lattice contribution to the specific heat, including the conduction electron $C_{el} = \gamma T$ and the phonon part C_{ph} . Since at higher temperatures (i.e. higher than ~ 50 K) $C_p(T)$ curves for Er and Lu compounds coincide almost exactly (see Fig. 2b), one can take LuZnSn_2 compound as a good reference material enabling the estimation of C_{lat} for ErZnSn_2 and other magnetic members of RZnSn_2 family. Hence, the subtraction of both curves gives $C_{pmagn}(T)$ contribution for Er compound and, in turn, integrating $C_{pmagn}(T)/T$ one can get the magnetic entropy contribution, S_{magn} , that reaches $15.88 \text{ J}/(\text{mol}\cdot\text{K})$, being less than $R\ln 16 = 23.05 \text{ J}/(\text{mol}\cdot\text{K})$, which is expected for the ground state $J = 15/2$ multiplet of Er^{3+} .

It is worth to note that the simple formula for $C_{lat} = C_{el} + C_{ph} = \gamma T + C_{ph}$ with C_{ph} given by the very well known Debye expression [13] in the form

$$C_{lat} = \gamma T + 9R \left(\frac{T}{\theta_D} \right)^3 \int_0^{\frac{\theta_D}{T}} \frac{x^4 e^x}{(e^x - 1)^2} dx$$

does not fit properly $C_p(T)$ curves obtained for Y and Lu compounds as well as that for Er (far above T_N) and this observation needs further analysis. It seems that the application of a more sophisticated analysis that includes a proper number of Einstein modes and anharmonic effects could improve remarkably the quality of such a fitting procedure.

Low temperature data for C_p/T obtained in the case of YZnSn_2 and LuZnSn_2 compounds are presented in Figs. 3a and 3b, respectively. They can be well fitted with a simple formula $C_p/T = \gamma + \beta T^2$ giving the electronic specific heat coefficients γ equal to $(5.04 \pm 0.30) \text{ mJ}/(\text{mol}\cdot\text{K}^2)$ for YZnSn_2 and $(5.75 \pm 0.20) \text{ mJ}/(\text{mol}\cdot\text{K}^2)$ for LuZnSn_2 , respectively. These derived values of γ are typical for nonmagnetic rare-earth intermetallics, which is in full agreement with the previous magnetic measurements [1] where no long range magnetic ordering has been observed for both compounds.

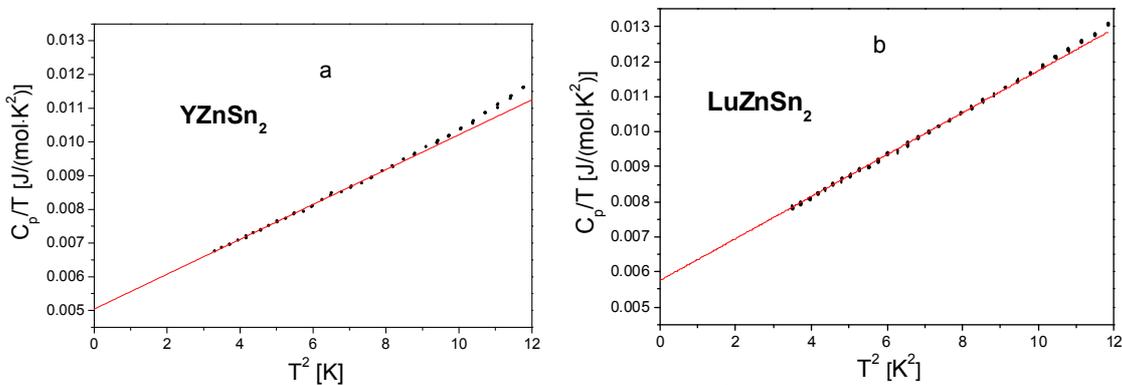

Fig. 3. Low temperature part of C_p/T dependencies on T^2 obtained for the YZnSn_2 (a) and LuZnSn_2 (b). The solid lines present the linear least-square fits used to derive the respective values of the specific heat coefficients γ and β for both compounds (see text).

The β coefficient is directly associated with C_{ph} , which at low temperatures ($T \ll \theta_D$) can be expressed as $C_{ph} = \beta T^3$ with $\beta = (12\pi^4/5)R/(\theta_D)^3$ [13] from where a Debye temperature θ_D value can be calculated. The β values obtained from the above discussed fits are $\beta = (5.17 \pm 0.40) \cdot 10^{-4} \text{ J}/(\text{mol}\cdot\text{K}^4)$ for YZnSn_2 and $\beta = (5.99 \pm 0.04) \cdot 10^{-4} \text{ J}/(\text{mol}\cdot\text{K}^4)$ for LuZnSn_2 . In turn, the knowledge of β allows to estimate approximate Debye temperatures for both compounds and they are as $\theta_D = (155.5 \pm 4.0) \text{ K}$ and $\theta_D = (148.0 \pm 3.0) \text{ K}$ for Y and Lu compounds, respectively. The obtained values are very characteristic for R-T-X intermetallics. Additionally, one can also notice that estimated in such a way both γ values, as well as Debye temperatures θ_D , are quite comparable supporting the idea that the electronic properties and the phonon dynamics are very similar for YZnSn_2 and LuZnSn_2 compounds what, in fact, could be expected.

Acknowledgements

The magnetic and heat capacity measurements were carried out with the PPMS - Quantum Design equipment purchased thanks to the financial support of the European Regional Development Fund in the framework of the Polish Innovation Economy Operational Program (contract no. POIG.02.01.00-12-023/08). This work was partially supported by FCT, Portugal, under the contract No. PTDC/CTM/102766/2008. The FCT Grant No. SFRH/BPD/34840/2007 for the research work of Yu.V. at ITN, Sacavém, Portugal is highly appreciated.
